ABSTRACT

Evidence is presented that the silver hake population along the Atlantic coast is comprised of two separate groups. One group inhabits the waters off the New England coast and the other is found off the southern New England, New York, and New Jersey coasts. Two characters, head length and pelvic fin length, gave consistent differences for separating these groups during two seasons of the year. The data were analyzed by appropriate F-tests in an analysis of covariance and by a T-test for the distance between regression lines.

INTRODUCTION

A program of research on the biology of the silver hake (*Merluccius bilinearis*, Mitchill) was initiated in 1955 at the Fish and Wildlife Service, Bureau of Commercial Fisheries, Biological Laboratory, Woods Hole, Massachusetts. This species is fished commercially in the coastal waters from Maine to New Jersey and is processed largely for human consumption with lesser amounts being used for animal food and industrial purposes. One of the research aims was to determine if the silver hake caught by the commercial fishing fleet consist of one or more than one population. In the present study, morphometric data from the Gulf of Maine, Rhode Island, New York, and New Jersey are compared.

Acknowledgments

The authors wish to acknowledge the statistical help given by William H. Callahan of the Woods Hole Biological Laboratory.

MATERIALS AND METHODS

Silver hake used in this study were collected from pound nets, weirs, and otter trawlers from Maine to New

Jersey. Additional collections were made on cruises of the *Albatross III* in 1955 and 1956. Care was taken to correctly identify the silver hake and not include the American or offshore hake, *Merluccius albidus*, in this study. The location and description of each sample are shown in figure 1 and table 1.

The characters measured conformed to the descriptions of Hubbs and Lagler (1947) and are listed in table 2. The fork length was used as the independent variable in all comparisons; all other characters measured were employed as dependent variables. The statistical methods outlined in Snedecor (1946) for the covariance analysis and a T-test described by Quenouille (1950) to determine the significance of the distance between regression lines were used.

The original data were plotted to determine the relationship of the various dependent variables on the independent variable. A linear relationship was found to exist between variables for silver hake from 26 to 38 centimeters. Accordingly, only those fish in the sample between 26 and 38 centimeters in length were used in this study and approximately 25 fish were collected in each 1-centimeter size group at each sampling location.

Figure 1.--Sampling locations and source of samples for the silver hake used in this study.

Quenouille outlines two assumptions that must be fulfilled in order to use the T-test between regression lines: (1) The variance of the samples must be comparable, when the larger variance of the two is divided by the smaller, the resulting F-ratio should not be significant; (2) the regression coefficients must not be significantly different. The above assumptions were fulfilled for head length and length of the pelvic fin only; all other parameters failed to meet these assumptions.

If conditions 1 and 2 are met then the variances and coefficients may be pooled and the two regression lines recomputed using a mutual regression coefficient. The difference between the lines may then be computed simply by subtracting values of one formula from that of the other. The difference is then tested to determine if it is significantly different from zero. An example of the application of this test using data from the present study is given in table 3.

To further determine whether or not there are significant differences between the silver hake collected from the Gulf of Maine and those from Rhode Island to New Jersey, covariance analyses of eight morphometric characters were calculated for each area. These analyses are summarized in table 4. Those characters showing a difference at the 1-percent level or higher were head length, length of the pelvic fin, length of the first ventral fin, and eye diameter. These four characters were used to separate the groups. The T-test was applied to only two of the characters, head length and length of the pelvic fin. The other two characters, eye diameter and length of the first ventral fin, were not applicable since the variance of the samples was too great.

RESULTS

Following Marr's (1957) suggestion, the term "group" will be used to define the various fractions of the population since the distinctive characteristics cannot be classed as being either phenotypic or genotypic.

Head Length

Covariance analysis between inshore and offshore samples collected in the Gulf of Maine was not significant (table 4). Assuming that the Gulf of Maine consists of only one group, these data were compared with samples taken from Nantucket Shoals (west) and the resulting "F" value was significant. The Gulf of Maine data were compared with the samples taken from Rhode Island, New York, and New Jersey, and the results of the covariance analysis were highly significant. However, no significant difference was found between the samples collected from Rhode Island and those taken from New Jersey, nor between the Nantucket Shoals and New York samples. The plotted regression lines of the samples collected from the Gulf of Maine, Rhode Island, and New York-New Jersey are shown in figure 2.

The results of the T-test for the distance between regression lines for the Gulf of Maine and the Rhode Island-New Jersey samples were found to be highly significant, as shown in table 5. However, a comparison between two closely associated areas, Rhode Island and New Jersey, was not significant. These results indicate that the silver hake in the Gulf of Maine are significantly different with regard to head length from the silver hake found along the southern New England, New York, and New Jersey coasts and that this parameter can be used to separate these two groups.

Length of Pelvic Fin

The plotted regression lines for length of the pelvic fin against total length are presented in figure 2. The Rhode Island and New Jersey samples

TABLE 3.--An example, using data on head length from the present study, showing how the Quenouille T-test for the separation of regression lines of similar slope can be employed for racial studies in fishery investigations

Parameter, location and date	F (formula 1) between variances	T (formula 2) between coefficients	T (formula 3) between lines
Gulf of Maine September 1955 New Jersey October 1955	1.386 NS	0.0166 NS	26.462**
Gulf of Maine April 1956 New Jersey April 1956	1.052 NS	0.0061 NS	32.495**

Formulae:

(1) $F = \dfrac{V \text{ (larger)}}{v \text{ (smaller)}} = \dfrac{\Sigma y^2 - \dfrac{(\Sigma xy)^2}{x^2}}{n-2}$ where $V = sy \cdot x^2$

(2) $T = b_1 - b_2$ where $(sdy \cdot x^2) / N_1 + N_2 - 4$

$$\sqrt{\dfrac{v_{1.2}}{N_1} + \dfrac{V_{1.2}}{N_2}}$$

(3) $T = \dfrac{\overline{Y}_1 - \overline{Y}_2 \; \hat{b} \; (\overline{x}_1 - \overline{x}_2)}{s\hat{y} \cdot x^2 \left(\dfrac{1}{N_1} + \dfrac{1}{N_2} + \dfrac{\overline{x}_1 - \overline{x}_2}{\Sigma x^2_1 \; \Sigma x^2_2} \right)}$

where $b = \dfrac{\Sigma x_1 y_2 + \Sigma x_2 y_2}{\Sigma x^2_1 + \Sigma x^2_2}$ and

$s\hat{y} \cdot x^2 = \dfrac{(\Sigma x_1 \cdot y_1 + x_2 \cdot y_2)^2}{\Sigma x^2_1 + \Sigma x^2_2}$

Symbols used are: ** - significant at the 1 percent level, and
NS - not significant.

do not differ significantly, but when compared with the Gulf of Maine collection the results were highly significant (table 4).

The T-test was also applied to this parameter and the comparisons with the Gulf of Maine with the total southern collection (Nantucket Shoals, New York, and New Jersey) were found to be highly significant (table 5).

Length of First Ventral Fin

Comparisons were made with silver hake collected in the northern area (Gulf of Maine) and those from Rhode

variance of these samples was also too large for the T-test.

CONCLUSIONS

The results of the analysis of the morphometric measurements used in this study indicate that two groups of silver hake may be distinguished, one from the Gulf of Maine and the other south of Cape Cod. Relative differences in head length, length of pelvic fin, length of ventral fin, and eye diameter clearly indicate that the samples taken from the major areas (Gulf of Maine, Rhode Island, New York, New Jersey) were not drawn from the same population. The amount of intermixing between the areas, if any, cannot be determined from the present data. Results from preliminary tagging experiments conducted in both areas have not indicated any movement of silver hake between areas.
